ABSTRACT

Fiber reinforced resin matrix composites have found increased usage in recent years. Due to the lack of service history of these relatively new material systems, their long-term aging performance is not well established. In this study, adhesive bonds were prepared by the secondary bonding of Scotch-Weld™ AF-555M between pre-cured adherends comprised of T800H/3900-2 uni-directional laminate. The adherends were co-cured with wet peel-ply for surface preparation. Each bond-line of single-lap-shear (SLS) specimen was measured to determine thickness and inspected visually for voids. A three-year environmental aging plan for the SLS specimens at 82°C and 85% relative humidity was initiated. SLS strengths were measured for both controls and aged specimens at room temperature and 82°C. The aging results of strength retention and failure modes to date are reported.

1. INTRODUCTION

Fiber reinforced resin matrix composites have been introduced increasingly in recent years for primary structural applications on military and commercial aircraft (e.g. A380, B787, YF-22). These materials offer advantages in weight savings without sacrificing strength and mechanical performance. Due to the lack of service history of these relatively new material systems, their long-term aging performance is not well established. In view of this potential issue, an Aviation Safety Program (ASP) was initiated under NASA's Aeronautics Research Mission Directorate (ARMD) in 2007. As a part of ASP, the Aircraft Aging and Durability Project (AADP) was formulated to characterize, predict and manage damage and degradation issues associated with aircraft aging. The focus of the AADP is aging and damage processes in "young" aircraft, rather than life extension of legacy vehicles, thus the emphasis of research is on the behavior of new composite and adhesive systems.

* This paper is declared a work of the U.S. Government and is not subject to copyright protection in the United States.

Previous work has demonstrated that high quality joints were bonded using a peel-ply surface treatment that serves to provide increasing surface roughness and prevents mould release agents and other materials from contaminating the surface [1-3]. In this approach, the peel-ply was co-cured as part of the top laminate ply and subsequently removed just prior to bonding. It was easily released by peeling off the adherend surface because of the non-stick nature of the carrier fabric substrate (typically a polyester or polyamide). Increasing surface roughness resulted in an increase in surface area, which allowed the adhesive to flow in and around the irregularities on the surface to form a mechanical interlocking bond. In the present study for an AADP subtask entitled “Bonded Joints for Construction and Repair”, the bonding surfaces were prepared by co-curing Toray T800H/3900-2 composite prepregs with a resin impregnated wet peel-ply. Single-lap-shear (SLS) specimens were bonded using AF-555M adhesive. Processing pitfalls for producing porosity-free, high quality bonds have been reported previously [4]. The behavior of on-going aging of SLS specimens in temperature/humidity chamber is reported herein.

2. MATERIALS[†]

The materials used in this study are presented in Table 1. Specifications have been reported previously [4]. All materials were used as-received without further treatments.

Table 1. Materials used in this study

Material Form	Material Designation	Supplier
Prepreg	T800H/3900-2	Toray
Adhesive	S/W AF-555M	3M
Wet peel ply	Hysol EA-9895	Henkel

3. EXPERIMENTAL

3.1 Fabrication of composite adherends

The composite adherend panel, 61 cm by 81 cm (24” by 32”) - $[0]_{16}$, was assembled by stacking up 16 plies of uni-directional T800H/3900-2 prepreg. A peel-ply strip of 61 cm by 5.1 cm (24” by 2”) was laid down on the top prepreg layer, perpendicular to the fiber direction and separated by a pre-determined distance shown in Figure 1a. This assembly was cured at 177°C (350°F) for 2 hours under 690 KPa (100 psi) in an autoclave with vacuum bagging.

3.2 Bonding of adherends

Peel-ply co-cured composite adherend panels were then cut into six 61 cm by 10.8 cm (24” by 4.25”) strips along the center of the 5.08 cm (2”) wide peel-ply as indicated in Figure 1a. The peel plies were then removed to expose the co-cured surfaces. Peel-ply surfaces were used as-peeled without any additional chemical cleaning or wiping. The surfaces were visually inspected

Figure 1. Schematic drawing illustrates lay-up, co-curing, trimming (Figure 1a, top view) and secondary bonding of composite/peel-ply/adhesive (Figure 1b, side view) in fabricating single-lap-shear specimens.

for residual fiber debris after the peel-ply was removed. The surface characteristics have been reported previously [4]. A 61 cm by 1.27 cm (24" by 0.5") strip of AF-555M adhesive was subsequently laid down on each exposed surface. A roller was used to help remove any trapped air by rolling and pressing down the adhesive onto the surface. The adhesive was then sandwiched by laying down the second half of the adherend panel. Shims were used to align and control the final bond-line thickness. The six-strip assembly (see Figure 1b) was then bagged and cured in an autoclave at 177°C (350°F) for 2 hours under 310 KPa (45 psi).

3.3 Preparation of the single-lap-shear (SLS) specimens

Co-cured strips measuring 61 cm by 12.7 cm (24" by 8") were cut into 2.5 cm by 12.7 cm (1" by 8") SLS specimens according to ASTM D1002-99 specifications [5]. Each bonded strip yielded 22 specimens, which were numbered as shown in Figure 2. A complete identification of a specimen is indicated by Panel ID-Strips ID-Specimen ID. In this way, the origin of each specimen can be traced back to the starting materials. A total of 66 specimens were fabricated from a single autoclave run.

Figure 2. Schematic drawing (top view) illustrates identification of single-lap-shear specimens. Panel ID is #1, bonded strip pair IDs are 2/3, 4/5 and 6/7 (see Figure 1), and specimen IDs for each bonded strip pair is numbered 1 to 22 from right to left

3.4 SLS strength measurement

SLS strengths were measured by a MTS test frame. Details of the testing have been reported before [4].

3.5 Aging chamber

The environmental chamber used was a MicroClimate™ model MCB-1.2 manufactured by CSZ (Cincinnati Environment Chamber). This chamber has a standard temperature range of -73°C to 190°C (-100°F to 375°F) and a maximum relative humidity (RH) of 95%. The aging condition selected in this study was 82°C (180°F)/85% RH [6]

4. RESULTS And DISCUSSION

Bond-line characteristics and thickness of each specimen were documented prior to aging or testing. A typical specimen with voids present in the bond-line is shown in Figure 3. One side of the bond-line exhibited no porosity, while the other side showed visible voids. For this study, each humidity aging time exposure would contain a mixture of specimens consisting of some that were void-free and some containing voids.

Specimens numbered 3, 11, and 20 in each bonded strip (see Figure 2) were selected to be tested at room temperature (RT) as controls before aging. Results for Panel #2 are shown in Table 2. Specimens from Strips 1 and 2 were void-free and exhibited SLS strengths which were consistently 30% above the nominal value of 35.9 MPa (5,200 psi) reported by the manufacturer

[7]; while Strips 3 and 4, and 6 and 7 yielded void-containing specimens, with strength values that were 85 to 95% of this nominal value. Results from another panel (Panel #4) which yielded void-free specimens are presented in Table 3. The SLS strengths measured were consistently over 10% of the nominal strength value. Whether the bond-line voidness is an effective discriminator for bond strength remains to be seen from the aging results reported below.

Figure 3. Visual evidence of porosity in the bond-line. Adhesive is sandwiched between top and bottom composite adherends

It was noted that Panel #4 yielded uniform bond-line thickness, while Panel #2 did not. The origin of bond-line variations came from the thickness variations among the bonding adherend strips. In an autoclave run, three sets of adherend strips were bonded using a single large caul plate, which made the control of bond-line uniformity difficult.

Table 2. RT strength values for Panel #2 control specimens

Strip ID	Specimen ID	Bond-line thickness, mil	SLS strength, MPa	% of nominal strength**
1/2	3	1	46.8	130

4.1 Aging plan

The 3-year aging plan is presented in Table 4. Specimens were selected according to the measured RT strengths of controls from each bonded adherend strips. Bond-lines were

photographed and characterized by 3 categories: Void-free, those containing 1-2 visible voids and those containing 3-5 visible voids. It is important to note that the voids are only visible along the bond edges. Specimens were too small for ultrasonic inspection of bubble entrapment within the bond-lines. Thus it was not possible to assess overall bond quality for each specimen. Five specimens in each aging group (i.e. exposure time) were randomly selected from these three categories and were also selected such that they were not derived from a single co-cured panel. Specimens were aged at 82°C (180°F) and 85% RH with pre-determined aging times. All specimens were labeled, baked-out at 66°C (150°F) for 1 hour to eliminate moisture, and weighed prior to placement in the aging chambers. Control specimens were wrapped in a plastic bag and “aged” in desiccators at RT. A total of 160 specimens were included. Tests of control and aged specimens were conducted at RT and 82°C (180°F). The test intervals were more frequent in the first year. Specimen weights after aging were recorded and fracture surfaces were examined after testing.

4.2 Results of control specimens “aged” in desiccators

Results of control specimens aged up to 4.2 months (125 days) in desiccators are tabulated in Table 5. Specimen grouping for each aging interval consisted of 5 specimens that were a mixture of void-free and specimens with voids. Strengths at RT and 82°C (180°F) for each aging time were measured and average strengths and strength retentions calculated.

Table 5. Strengths of control specimens aged in desiccators at RT

Specimen ID	No. of voids in bone-line	Bond-line thickness, cm (mil)	Days aged	Test temp, °C	SLS strength, MPa	Failure mode**	Avg. strength, MPa	% RT strength retention*

**Failure modes: CF – cohesive, TLC – thin layer cohesive, LFT – light fiber tear, FT – fiber tear, AS – adhesive starvation. Numerical values depict percentages.

Table 6. Strengths of control specimens aged in desiccators at RT

Specimen ID	Days aged in desiccators	Bond-line characteristics	Test temp, °C	Avg. strength, MPa	% Strength retention*
A0	0	Void-free	RT	37.3 ± 0	104
			82	31.1 ± 0	87
	125		RT	41.1 ± 0	114
			82	31.1 ± 0	87
A180	0	Void-containing	RT	37.9 ± 3.0	106
			82	30.2 ± 2.3	84
	125		RT	35.5 ± 7.1	99
			82	32.0 ± 0.8	89

*Based on nominal strength 35.9 MPa (5,200 psi) from the supplier

As previously observed, SLS strength values were independent of bond-line thickness. These results were further re-grouped for clarity by specimens with and without voids in Table 6. Void-free fresh specimens (i.e., specimens A0) exhibited RT strength of 37.3 MPa (5,459 psi) which is 104% of the nominal 35.9 MPa (5,200 psi) from the supplier. Strength of 31.1 MPa (4,380 psi) was measured at 82°C (180°F) and represented 87% retention of the RT value. Void-free specimens aged in the desiccators for 4.2 months (125 days) yielded strength of 41.1 MPa (5,954 psi) and 31.1 MPa (4,505 psi) at RT and 82°C (180°F), and represented strength retentions of 114% and 87%, respectively. As expected, RT aging in desiccators had no apparent effect on void-free specimens as both strength and strength retention at RT and 82°C (180°F) were unchanged.

Void-containing specimens aged in desiccators behaved similarly to those void-free specimens reported above (see Figure 6). Apparently bond-line voidness is not an effective discriminator in this aging condition. It was also noted that the standard deviations were large in all cases for reasons that are unclear at this time.

4.3 Results of strength retention for specimens aged in humidity chambers

Results of specimens aged at 82°C/85% RH up to 4.2 months (125 days) are tabulated in Table 7.

Table 7. Strengths of specimens aged in humidity chambers

			82	21.8 ± 3.4	61
A90	95		RT	28.4 ± 2.7	79
			82	23.3 ± 5.6	65
A180	125		RT	29.3 ± 1.1	82
			82	23.6 ± 1.8	66

*Based on nominal strength 35.9 MPa (5,200 psi) from the supplier

Percent strength retention measured at RT in Table 8 was plotted in Figure 4 for comparison between void-free and void-containing specimens. Strength retention for the void-free specimens was clearly better than those containing voids. Aged void-free specimens exhibited 100% strength retention up to 3.2 months (95 days) in the humidity chambers and 90% strength retention after 4.2 months (125 days). On the other hand, the void-containing specimens exhibited 90% strength retention after only 1.2 months (35 days) of aging; then rapidly dropped to 80% retention afterwards.

Percent strength retention measured at 82°C (180°F) in Table 8 was plotted in Figure 5. In this case, strength retention for the void-free specimens was only marginally better than for those containing voids. Aged void-free specimens maintained 85% strength retention up to 1.2 months (35 days), and then began to diminish. For the specimens containing voids, the strength retention was noted to drop immediately and reached 60% level at 1.2 months (35 days) days of aging. The void-containing specimens were more susceptible to moisture ingress and consequently began to degrade quicker. After 35 days aging, strength retention for both void-free and void-containing specimens remained at ~65% up to 4.2 months (125 days) of aging.

Figure 4. Percent strength retention measured at RT for void-free vs. void-containing specimens aged in 82°C/85% RH chambers up to 125 days.

Figure 5. Percent strength retention measured at 82°C for void-free vs. void-containing specimens aged in 82°C/85% RH chambers up to 125 days.

Percent strength retention in Figure 5 was comparable between void-free and void-containing specimens aged after 35 days, with strength retention values leveling off in spite of the bond-line quality. This observation raised the possibility that voids were actually entrapped in the bulk of

the “void-free” specimens but were not visibly detectable. These specimens were only examined optically along the bond-line edges as shown in Figure 3.

The poor strength retention observed in this study requires further investigation to determine if bond quality is the cause. Since the bonded area of these specimens was too small for ultrasonic inspection, this issue will be addressed in future work by fabricating specimens with larger bond areas. Additional SLS specimens will be fabricated, aged and tested following ASTM D5868 [8] which specifies a 6.5 sq-cm (1 sq-in) shear area versus the 3.2 sq-cm (0.5 sq-in) (ASTM D1002) used in the current study. This larger bonded surface area will retard moisture ingress and allow for bond quality investigation by non-destructive techniques such as c-scan. In addition, a lower aging temperature of 71°C (160°F) under 85% RH will be investigated.

4.4 Failure modes of SLS specimens

Fracture surface failure modes were characterized according to ASTM D5573 [9]. For specimens aged up to 125 days, the failure modes were dominated by cohesive failure and thin-layer cohesive failure.

5. SUMMARY

SLS specimens were fabricated using state-of-the-art carbon fiber/epoxy laminates and AF-555M adhesive. The adhesive bond was cured in an autoclave under 310 KPa (45 psi) at 177°C (350°F) for 2 hours. Fresh specimens, with either void-free or voided bond-lines, yielded RT SLS strengths which were consistently >10% higher than the nominal 35.8 MPa (5,200 psi), and 85% strength retention when measured at 82°C (180°F) for this adhesive.

A three-year aging plan was initiated in 82°C (180°F)/85% RH chambers. Specimens were removed at discrete aging times and SLS strengths measured. Bond-line characteristics and thickness, and specimen weights before and after aging were documented. Each aging time was composed of a mixture of void-free and void-containing specimens for a total of five specimens. Control and aged specimens were tested under RT and 82°C (180°F) conditions.

For the controls stored in desiccators, both RT and 82°C (180°F) strength values remained unchanged after 4.2 months (125 days) for both void-free and void-containing specimens.

For the aged specimens in humidity chambers, RT strength retention for the void-free specimens was clearly better than for those with voids. Void-free specimens exhibited 100% strength retention with up to 3.2 months (95 days) of aging and 90% retention after 4.2 months (125 days) of aging. On the other hand, specimens containing voids exhibited 90% strength retention after only 1.2 months (35 days) of aging; subsequently, strength then diminished more rapidly.

The 82°C (180°F) strength retention for the void-free specimens were only marginally better than those with voids. Void-free specimens maintained 85% strength retention up to 1.2 months (35 days) of aging before diminishing.

The poor strength retention behavior after aging at 82°C (180°F) and 85% RH observed in this study requires further investigation to determine if porosity in the bulk of the specimens is the cause of degradation of properties.

6. ACKNOWLEDGEMENT

The authors gratefully acknowledge the contributions from colleagues from the AADP team in the Advanced Materials and Processing Branch, NASA Langley Research Center during the

course of this study. In particular, valuable advice and discussions from Dr. Joseph G. Smith, and diligent specimen fabrication from Kelvin G. Boston.
